

Crisis Learning

Cameron Pfiffer

June 2, 2021

Howdy hey, gang. The goal of this document is to describe the rough shape of an economy with a simple state-based structure.

1 Model styles

In all models, it is assumed that the initial state distribution is categorically distributed with probabilities $\Pi = [\pi_1, \pi_2, \dots, \pi_Q]$ for Q states.

The state transition matrix is given by A . It is assumed that all know the transition matrix.

1.1 Simple Gaussian

Figure 1.1 demonstrates an extremely simple economy where a latent state variable S_t evolves over time. In each possible state $S_t \in \mathbb{S}$, the location and scale parameters ($\mu(S_t)$ and $\Sigma(S_t)$) of the Gaussian payoff vector f_t may vary:

1. The degenerate constant mean/variance condition $\Sigma(S_t) = \Sigma$ and a changing mean payoff vector, $\mu(S_t) = \mu$.
2. A constant variance term $\Sigma(S_t) = \Sigma(S'_t) = \Sigma$ and a changing mean payoff vector, $\mu(S_t) \neq \mu(S'_t)$.
3. A varying variance term $\Sigma(S_t) \neq \Sigma(S'_t)$ and a constant mean payoff vector, $\mu(S_t) = \mu$.
4. The "everything changes" case where both $\mu(S_t)$ and $\Sigma(S_t)$ vary.

Regardless of the choice of method above, going forward I will simply denote means and variances as μ and Σ to reduce notational costs, but keep in mind that they are implicit functions of macroeconomic state S_t .

Investors do not observe all elements of f_t simultaneously. Rather, they observe them sequentially — denote a partition of f_t after $n \leq N$ firms have been observed with $f_{t,1:n}$. Write the distributions of observed payoffs $f_{t,A}$ and the payoffs yet to be observed $f_{t,B}$ as the partitions

Figure 1: Depiction of the underlying economic process. S_t is a Markov state process drawn from $S_t \sim P(S_t, S_{t-1})$, while f_t is a multivariate Gaussian of dimension N (one for each firm). Payoffs f_t are Gaussian only conditional on S_t , i.e. $f_t | S_t \sim \mathcal{N}(\mu(S_t), \Sigma(S_t))$.

$$\begin{aligned} f_t &= [f_t^A \quad f_t^B]' \\ f_t^A &\sim \mathcal{N}(\mu^A, \Sigma^A) \\ f_t^B &\sim \mathcal{N}(\mu^B, \Sigma^B) \end{aligned}$$

where

$$E[f_t | S_t] = \mu = \begin{bmatrix} \mu^A \\ \mu^B \end{bmatrix}$$

The superscripts A and B are used to indicate a subsetting operation where $\mu^A = \mu_{1:n}$ and $\mu^B = \mu_{n+1:N}$. The covariance matrices can be similarly partitioned into a block matrix

$$\text{Var}[f_t | S_t] = \Sigma_{N \times N} = \begin{bmatrix} \Sigma_{n \times n}^A & \Sigma_{n \times N-n}^{AB} \\ \Sigma_{N-n \times n}^{BA} & \Sigma_{N-n \times N-n}^B \end{bmatrix}$$

Note, however, that f_t^A is observed, and is no longer a stochastic variable. However, it was *drawn* from a distribution correlated to f_t^B , and thus can be used as conditioning information to more precisely determine the distribution of the payoffs to be revealed, f_t^B . It can be shown that, conditional on observing f_t^A , the distribution of f_t^B is

$$f_t^B | f_t^A, S_t \sim \mathcal{N}(\bar{\mu}^B, \bar{\Sigma}^B)$$

for conditional parameters

$$\begin{aligned} \bar{\mu}^B &= \mu^B + \Sigma^{BA}(\Sigma^A)^{-1}(f_t^A - \mu^A) \\ \bar{\Sigma}^B &= \Sigma^B + \Sigma^{BA}(\Sigma^A)^{-1}\Sigma^{AB} \end{aligned}$$

Actually
show this?

I assume that, for any state, the covariance matrix of firm payoffs is drawn from an inverse Wishart distribution parameterized by the shape matrix Ω and precision ν . The distribution of Σ holds even for cases where the covariance matrix does not change across states¹. The matrix Ω determines the fundamental “shape” of the covariance structure, in that the mean of the distribution of Σ is

$$E[\Sigma \mid S_t] = \frac{\Omega}{\nu - N - 1}$$

The average *covariance* can vary substantially in terms of scale as ν changes, but the average *correlation* remains the same regardless of ν . Any two draws Σ_1 and Σ_2 can have highly varied behavior. For example, Σ_1 might suggest a negative correlation in the payoffs of two firms, while Σ_2 could suggest a positive correlation. The inverse Wishart distribution is advantageous because the covariance matrix governing firm payoffs can vary meaningfully between states, and the distribution’s properties are well-known.

The joint density

The physical joint density of the economy is defined in terms of a particular set of states $\mathbf{S} = S_0, \dots, S_t$ and a set of payoffs $\mathbf{f} = f_0, \dots, f_{t-1}, f_t^A$. The chain rule of probability allows us to factor this probability as

$$P(\mathbf{S}, \mathbf{f}, \Sigma, \mu) = P(\mathbf{f} \mid \mathbf{S})P(\Sigma, \mu \mid \mathbf{S})P(\mathbf{S})$$

The second part of the term above is a function of A and Π . The first element of a particular path S_0, \dots, S_t is drawn using probabilities Π , and the underlying state transitions according to the entries in the matrix A .

$$P(S_0, \dots, S_t) = P(\mathbf{S}) = P(S_0)P(S_1 \mid S_0) \dots P(S_t \mid S_{t-1})$$

The term $P(S_0)$ is either π_1 or π_2 , depending on S_0 . Denote this as $\pi(S_0)$. Additionally, denote the transition probability from S_{t-1} to S_t as $A(S_{t-1}, S_t)$. The above equation can then be rewritten as

$$P(\mathbf{S}) = \pi(S_0) \prod_{i=1}^t A(S_{i-1}, S_i)$$

The state space of \mathbf{S} is Q^t . Each “path” of states \mathbf{S} maps to an element on a discrete table of probabilities. Computing this table is computationally difficult but can be achieved with robust forward-backward passes.

¹In models where the covariance matrix changes with state (cases 3 and 4), the inverse Wishart distribution can still be used as the distribution collapses with certainty as $\nu \rightarrow \infty$.

Prices

I'm not sure how to generate prices in this setup. I need to have some way of prices for different assets changing after the payoff is received, to capture learning-driven price drift.

The first way to do this is simply to recognize that states are persistent in some way, so $S_t = H$ implies that the probability of having future high states is also high. In this case, the risk-neutral price of an asset is simply the discounted sum of future expected payoffs:

$$P_{i,t} = E \left[\sum_{j=1}^{\infty} \rho^j f_{i,t+j} \right]$$

Alternatively, it might be more canonical to use the SDF approach here. The SDF price has a couple of advantages. First, prices are set in accordance with risk aversion and with differences across agents. Second, I intend to use a computational approach anyway, which means that the distribution of M_t doesn't have to be formally specified, but can be directly calculated from preferences.

$$P_{i,t} = E \left[\sum_{j=1}^{\infty} M_{t+j} f_{i,t+j} \right]$$

I could also apply a noisy rational equilibrium price which is linear in various signals. In Kazperczyk et al. (2016), this takes the form of an equilibrium price

$$\tilde{p} = \frac{1}{r} (A + Bz + Cx)$$

for factor shocks z and supply shocks x . The issue with this particular model is that it (a) only works under very specific assumptions that I don't quite see how to expand yet and (b) is a strictly linear equilibrium price. The linearity causes all kinds of weird corner solutions.

Questions:

1. Can I just compute everything?
2. Main topic/focus: learning across crises, attention + learning, how do rational inattention vs. sparsity impact things differently?
